

## VV Cep OUTSIDE ECLIPSE

POLLMANN, E.

email: ErnstPollmann@aol.com

The 1997-1999 eclipse of the binary VV Cep gave researchers further opportunities to analyze the system. Bauer, Bennett and Brown (1998) attributed strong, double-peaked emission lines such as Mg II and Fe II in the ultraviolet range 2700-3000 Angstroms to an expanding atmosphere. They also reported that the hot B star was, during one orbital period, shrouded in a rich absorption spectrum of singly ionized elements. According to Leedj arv, Graczyk, Mikolajewski and Puss (1999) the eclipse occurred 68 days later than predicted which may indicate an orbital period change due to mass transfer between the M and B stars. Further, they suggested that the cooler object may be an asymptotic giant branch star instead of a supergiant. Graczyk, Mikolajewski and Janowski (1999) came to the same conclusion. They found masses for the M and B stars of about 2.5 and 8 solar masses, respectively, with a total mass ejection of 0.008 solar mass and a loss rate of  $4 \times 10^{-4}$  solar mass per year.

In an earlier paper (Pollmann, 2001) I presented observations of H $\alpha$  emission strength in VV Cep, as measured in equivalent width (EW), from JD 2450202 to 2452061. The rate of sampling was high enough to reveal the eclipse in detail and to show asymmetric distribution of H $\alpha$  intensity across the accretion disk as determined at the times of ingress and egress.

In this paper I report on continued observations in the period JD 2452061 to 2452619. I used the 200 mm Schmidt-Cassegrain telescope at the Cologne Stargazer's Association Observatory in the mountains of Odenthal, Germany (latitude: 51 $^{\circ}$ 02', longitude: 7 $^{\circ}$ 15'). My spectrograph with diffraction grating has a dispersion of 0.39Å/pixel and a wavelength range of 6400Å to 6700Å. The detector is a Kodak KAF400 sensor with 768 $\times$ 512 pixels. Pixels are 9 $\times$ 9 micrometers. The resolving power is  $R = 8200$ . Data after JD 2451852 and discussed by Pollmann (2001) have also been observed with this instrument. Current results reveal apparent stochastic variation in H $\alpha$  EW with a range of about 10Å outside eclipse. Despite these dispersions the EW seems to have increased after the eclipse within the period represented here with an upward gradient of approximately 1 Å/200d. There is also variability on a timescale of many hundreds of days. In Figure 1 the latter is identified by a linear fit to post-eclipse observations. Table 1 collects the observations that is also available electronically at the IBVS website as 5398-t1.txt. Exploration of both types of change is a likely project for the years leading up to the next eclipse that begins in 2017.

Wright (1977) observed H $\alpha$  emission out of eclipse between 1956 and 1976. I determined V/R ratios from his Figure 4 plots and show them in Figure 2 along with my V/R

results. Wright observed nearly an entire orbit with relatively few observations, while I was limited to phases from 0.14 to 0.24 with relatively more observations starting from JD 2451852. Prior to this date the resolution of the observed spectra did not allow to obtain V/R ratios. Figure 2 shows a phase-related cycle of change in V/R. In the short but significant range in which we overlap, my results agree with the pattern of rapid decrease detected by Wright. Erratic, short-term change in V/R is also indicated. Line profiles for my first and last observations appear in Figure 3. Table 2 presents all the V/R observations. I continue to observe H $\alpha$  emission in VV Cep and will report again in the future.

**Figure 1.** H $\alpha$  equivalent width as a function of time for VV Cep before, during and after the 1997-1998 eclipse.

**Figure 2.** V/R ratio for the H $\alpha$  emission line as a function of orbital phase as independently observed by Wright and Pollmann.

**Table 1.** H $\alpha$  equivalent widths

JD 2450	EW [Å]	JD 2450	EW [Å]	JD 2450	EW [Å]	JD 2450	EW [Å]
